Abstract—Advancement in wireless technologies and extended the use of wireless devices demand more and more infrastructure less networks like mobile ad hoc networks. As mobile adhoc network applications fan out security emerges as a central requirement. Wireless networks gain higher performance by using network coding. Network coding is a promising generalization of routing, which allows a node to generate output messages by encoding its received messages. However network coding also introduces new attacks such as wormhole attack, sabotage the performance gain of network coding. Since the characteristics of the network coding system are distinctly different from traditional wireless networks. In wormhole attack malicious node records control traffic at one location and tunnels it to another compromised node, possibly far away, which relays it locally. A centralized algorithm proposed to detect wormholes and show its correctness attendant For the distributed wireless network, DAWN, a Distributed detection Algorithm against Wormhole in wireless Network coding systems is proposed by delving into the change of the flow directions of the innovative packets caused by wormhole. Both the algorithms use node centric information instead of packet centric information, as the underlying network use network coding. Simulation results on NS 2 exhibit the effectiveness of the proposed algorithms in detecting wormhole attacks.

Keywords—centralized algorithm, distributed algorithm, expected count of transmission.

I. INTRODUCTION

Network coding is a technique which can be used to improve a network throughput, efficiency and scalability. Future networks are expected to move from traditional routing schemes to network coding based schemes, which have created a lot of interest both in academia and industry in the recent years. Under the network coding paradigm, intermediate nodes store and forward packets as original. In contrast, in wireless network coding systems, the forwarders are allowed to apply encoding schemes on what they receive, and thus they create and transmit new packets. The idea of mixing packets on each node takes good advantages of the opportunity, diversity and the broadcast nature of wireless communications, and significantly enhances system performance[1],[2].This type of communication has proved to be more robust to packet losses, be resilient to network changes such as dynamic topologies, and improve the overall throughput.

To investigate wormhole attacks in wireless network coding systems, we focus on their impact and countermeasures in a class of popular network coding scheme—the random linear network coding (RLNC) system. In this system, in order to best utilize resources, before data transmissions, routing decisions (i.e., how many times of transmissions a forwarder should make for each novel packet) are made based on local link conditions by some test transmissions. Since in wireless network coding systems the routing and packet forwarding procedures are different from those in traditional wireless networks, the first question that we need to answer is: Will wormhole attacks cause serious interruptions to network functions and downgrade system performance? Actually no matter what procedures are used, wormhole attacks severely imperil network coding protocols. In particular, if wormhole attacks are launched in routing, the nodes close to attackers will receive more packets than they should and be considered as having a good capability in help forwarding packets. Thus they will be assigned with more responsibility in packet forwarding than what they can actually provide. Furthermore, other nodes will be correspondingly contributing less. This unfair distribution of workload will result in an inefficient resource utilization and reduce system performance.

Wormhole attacks launched during the data transmission phase can also be very harmful. First, wormhole attacks can be used as the first step towards more sophisticated attacks, such as man-in-the-middle attacks and entropy attacks. For example, by retransmitting the packets from the wormhole links, some victim nodes will have to process much more non-innovative packets that will waste their resources; these constitute entropy attacks. Second, the attackers can periodically turn on and off the wormhole links in data transmissions, confusing the system with fake link condition changes and making it unnecessarily rerun the routing process. To further quantify the impact of wormhole attacks in wireless network coding systems, we perform extensive experiments and investigate the results.

The main objective of this paper is to detect and localize Wormhole attacks in wireless network coding systems. The major differences in routing and packet forwarding rule out using existing countermeasures in traditional networks [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16]. In network coding systems like
A centralized algorithm is proposed to detect wormholes leveraging a central node in the network. For the distributed scenarios, a distributed algorithm is proposed, DAWN, to detect wormhole attacks in wireless intra flow network coding systems. In DAWN, during the transmission tunnel is called a wormhole link. The packet loss rate on the wormhole link is negligible. The kinds of wormhole links can be various, such as an Ethernet cable, an optical link, or a secured long-range wireless transmission. When the wormhole attack is initiated, the attackers can capture data packets on either side, forward them through the wormhole link and rebroadcast them on the other node. Here each node includes the normal nodes in the wireless network and the central administrator, which presents in our centralized algorithm.

Linear network coding (LNC), especially random linear network coding. Linear network coding permits each node in the network to pass on the combinations of the received data, in order to optimize the information capacity. Let \( r_1, r_2, \ldots, r_n \) denote the received data, and \( s \) be the encoded data to be passed to another node. We can obtain the combination \( f \) based on the received data based on Equation (1).

\[
S = f(r_1, r_2, \ldots, r_n)
\]  
(1)

For RLNC, \( f \) in Equation (1) is a random linear combination in the field \( GF(2^n) \).

\[
\sum_{j=1}^{n} a_j r_j
\]  
(2)
A.THE CENTRALIZED ALGORITHM

We propose the centralized algorithm, which utilizes the ECT metric and the order of rank increment to detect wormhole attacks. In order to protect the validity of our method, we also introduce the public cryptographic scheme for the network. For each forwarding node in RLNC network, receiving the innovative packet will cause the rank of the previously received packets increases by one. We also find that the nodes with lower ECTs will be more likely to receive innovative packets (i.e., increase the rank) than other nodes. On the other hand, wormhole links will make some nodes receive innovative packets (i.e., increase the rank) much earlier that they should. Thus, in the proposed centralized algorithm, we explore the order of rank increments in order to detect the wormhole links.

Basically, in RLNC, when an innovative packet is sent from the source node, the nodes near the source node are more likely to receive the innovative packets earlier than the nodes that are far from the source node. Also, we have demonstrated ECT is a proper metric to measure the distances between each node and the source node. Thus, the nodes with low ECTs can probably receive the innovative packets earlier. However, the existence of wormhole link intuitively changes the normal network topology since the innovative packets can be transmitted through the wormhole link directly and safely, and thus the nodes around the remote side of the wormhole link can receive the novel packets earlier than expected. With a wormhole link, the order of the rank increments among the nodes will be significantly changed.T o illustrate the significant changes, we have a RLNC simulation for the centralized algorithm, we set up a central node, which owns the authority to gather information from all the nodes in the network, and we run a wormhole detection algorithm based on the rank increasing information on the central node. Each node is responsible to record the time when the rank of the received packets increases and then generates a report, which includes the details such as the time, the node address, and the rank. Each node delivers the reports to the central node via common unicast.

Based on the intuitions above, we propose Algorithm 1, the centralized algorithm to detect wormhole attacks on the central node. In Algorithm 1, the central node chooses an event of rank change, i.e., the rank increment from $i$ to $i + 1$, and then searches the received reports to find all the related ones. Then we compare the time order of ECTs with the ascending ECT sequence and calculate the distance between them. If the distance exceeds the threshold, we decide there exists wormhole attack, and release the warning. At last, we update the bound of the distance for the next detection, in order to make our algorithm adaptive.

Algorithm 1: The Centralized Algorithm

Input: $T$: the reports from all the nodes in the network $G$, $D$: the number of dimensions of the code vector space, $\text{Normal}$: the normal distance, $\text{Threshold}$: the threshold of alert.

Output: whether there exists a wormhole attack in the network $G$, the updated $\text{Normal}$.

Step 1: Randomly select a rank $r \in [1, r]$ and $\tau$ should be small enough, i.e., $1 < \tau < 5$.

Step 2: Let $T_\tau$ be the set of the reports whose rank increments are from $r-1$ to $r$.

Step 3: Sort $T_\tau$ into a sequence $T_\tau^r$, s.t. the values of ECT in $T_\tau^r$ are ascending.

Step 4: Let $L_\tau$ be the sequence of ascending ECTs in $T_\tau^r$.

Step 5: Sort $T_\tau$ into a sequence $T_\tau^r$, s.t. the values of time in $T_\tau^r$ are ascending.

Step 6: Let $L_t$ be the sequence of ECTs in $T_\tau$, while preserving the order.

Step 7: Distance $\leftarrow$ Calculate - Distance $(L_e, L_t, \lvert V \rvert)$.

Step 8: if $\text{Distance} > \text{Threshold}$ then

Step 9: Find out the addresses of the nodes with the most aberrant ECTs.

Step 10: Release a warning of wormhole attack.

Step 11: end if

Step 12: Update the value of $\text{Normal}$ using $k$-means.

In Algorithm 1, each report $t$ is a tuple as Equation (3): $t = (\text{time, addr, ECT, rank, } K_{\text{pub}}, \text{sig})$ (3) Here, time denotes the time stamp of the rank increment; addr denotes the address of the node who sends the report; ECT is the ECT of the reporting node; the value rank means the rank increased from rank - 1 to rank. $K_{\text{pub}}$ is the public key of the reporting node. sig is the digital signature of the report. The signature can be calculated by hashing function to obtain the abstract of the plain data $P = (\text{time, addr, ECT, rank, } K_{\text{pub}})$ and then encrypt the abstract using secret key $K_{\text{sec}}$ of the local node. The result is the signature sig. In Algorithm 1, $\text{Tr}$ denotes the set of the reports of rank increment from $r-1$ to $r$.
B. THE DISTRIBUTED DETECTION ALGORITHM

We consider a practical scenario where centralized authority cannot be found. We propose DAWN, a distributed algorithm to detect wormhole attacks in wireless network coding systems. The basic idea of DAWN is based on the two neighbor nodes u and v in the network satisfying ECT (u) < ECT (v). For any two nodes in the neighborhood, the one with lower ECT is supposed to receive novel packets earlier than the other one with high probabilities. In other words, innovative packets are transmitted from low ECT nodes to high ECT nodes with high probabilities. In order to monitor the innovative packets transmission direction, nodes will work collaboratively. In particular, DAWN has two phases on each node: 1) Report phase. As shown in Algorithm 2, for each node, it broadcasts the report r (u, v, 0) if it receives novel packets u received from each neighbor in the last batch; d: the threshold on ECT difference. Output: s, the local observation result for each neighbor v; N (u) Report messages if any.

Algorithm 2 Report Function

Input: N (u) the set of u’s neighbors; the number of the novel packets u received from each neighbor in the last batch; d: the threshold on ECT difference.
Output: s, the local observation result for each neighbor v ∈ N (u) Report messages if any.

Step 1: for v ∈ N (u) do
Step 2: Denote p, the number of novel packets that u received from v during the last batch.
Step 3: if ECT (v) – ECT (u) < δ AND p > 0} then
Step 4: u broadcasts the report r (u, v, 0)
Step 5: Note r (u, v, 0) represents the report sent from u about
Suspicious wormhole behavior of v, with hop count 0.
Step 6: s, = 1;
Step 7: else
Step 8: s, = 0;
Step 9: end if
Step 10: end for

Report phase. As shown in Algorithm 2, for each node, it will suspect that one neighbor is an attacker if it receives novel packets from the neighbor but the ECT of this neighbor is much higher than that of itself (i.e., the distance between the ECTs is greater than the threshold d). It sends its judgment as a report to its neighbors.

Algorithm 3: The Distributed Detection Algorithm for Wormholes in Wireless Network Coding Systems (DAWN) on Node u

Input: R: the set of reports received in the last batch, N (u): the set of u’s neighbors, s: the local observation result of each neighbor j ∈ N(u), d: the threshold.

Output: Detected wormhole attackers in N (u), if any.

Step 1: for each report r (i, j, k) ∈ R do
Step 2: if ECT (j) – ECT (i) ≤ δ OR i ∈ N (j) then
Step 3: Discard this report;
Step 4: else
Step 5: if j ∈ N (u) then
Step 6: s, = s, + 1
Step 7: end if
Step 8: if k < 2 then
Step 9: Forward this report r (i, j, k + 1);
Step 10: end if
Step 11: end if
Step 12: for each v ∈ N (u) do
Step 13: if C (v) = {i | i ∈ N (v) s.t. ECT (v) – ECT (i) ≤ δ 
Step 14: if s, ≥ | C (v) | + 1 / 2 then
Step 15: Mark v as a detected wormhole attacker, and block any traffic from or to node v in future batches.
Step 16: end if
Step 17: end if
Step 18: end for

Detect phase. Algorithm 3 presents the pseudocode of the Detect phase of DAWN. For each node in the Detect phase, it receives reports from the judge nodes of any potential attackers. It first examines whether a report is from a valid judge node. If so, it will forward the report unless it has already been forwarded twice. Three-hops of the reports make sure that more (reachable) neighbors of the potential attacker will hear this report. The detection algorithm on each node accumulates and calculates the number of its judge nodes who send report about the reported potential attacker in the current batch. If the number of judge nodes compose the majority, the node will make the decision that the attacker is involved in a wormhole attack and block it from future communications.
V SIMULATION RESULTS

Performance Evaluation

In this section, evaluate the performance of simulation. We are using the x graph for evaluate the performance. We choose the some evaluation metrics: Packet received ratio – the ratio of the total number of packets received by the destination node to the number of packet sent by the source, and also calculate the Packet Loss Ratio and End to End Delay. Along these evaluation metrics we have to evaluate the simulation performance in x graph.

Packet Received Ratio:

Fig 5.1 graph of Packet Received with Existing and Proposed Scheme

Packet Loss Ratio:

Fig 5.2 graph of Packet Loss with Existing and Proposed Scheme

VI CONCLUSION

In this work, we have investigated the negative impacts of wormhole attacks on wireless network coding systems. We have proposed two algorithms that utilize the metric ECT to defend against wormhole attacks. We have proposed a Centralized Algorithm that assigns a central node to collect and analyze the forwarding behaviors of each node in the network, in order to react timely when wormhole attack is initiated. We have proven the correctness of the Centralized Algorithm by deriving a lower bound of the deviation in the algorithm. We have also proposed a Distributed detection Algorithm against Wormhole in wireless Network coding systems, DAWN. DAWN is totally distributed for the nodes in the network, eliminating the limitation of tightly synchronized clock. DAWN is efficient and thus it fits for wireless sensor network. For both centralized and distributed algorithms, we have utilized the digital signatures to ensure every report is undeniable and cannot be forged by any attackers. The simulations have shown that the pro-posed algorithms can detect the malicious nodes participating in wormhole attack with high successful rate and the algorithm is efficient in terms of computation and communication overhead.
