Abstract- In this paper a versatile ac-ac power converter is proposed based on characterization of algorithm that can be utilized as a control device for Custom Power applications. The converter has the ability to regulate bus voltage through voltage sags. The dynamic voltage restorer is a definitive solution to address the voltage-related Power Quality problems. Conventional topologies operate with a dc link, which makes them bulkier and costlier; it also imposes limits on the compensation capability of the DVR. In the proposed scheme there is no storage device is employed, these topologies require improved information on instantaneous voltages at the point of common coupling and need flexible control schemes depending on these voltages. Therefore, a control scheme for DVR topologies with an ac-ac converter, based on the characterization of algorithms is proposed in this paper to mitigate voltage sags with phase jump. The proposed converter connected in three phase system in interconnected manner. The scheme is tested on an interphase ac-ac converter topology to validate its efficacy. Detailed simulations to support the same have been carried out in MATLAB, and the results are presented.

Index Terms – AC-AC Converter, Power Quality, Voltage Disturbances, Transposed Connection, DVR.

I.INTRODUCTION

Among different types of disturbances occurring in power system, voltage sag is known to produce the most devastating impact on the loads. Studies show that 92% of all disturbances in the electrical power distribution systems are voltage sags, transients, and momentary interruptions [1], [2]. More than 1500 distinct events studied by “i-grid.com” (mostly from large industrial plants located around the U.S. and Canada) were analyzed in detail [3], the statistical survey of the measured events, and indicates that 63% of the disturbances were single line-to-ground (SLG) faults and 11% were line-to-line (LL) faults [4]. Though symmetrical faults (Symm) were 6%, deep symmetrical three-phase voltage sags were very rare [1]. Most of the three-phase symmetrical faults create symmetrical sag depth less than 50%. Increasing use of loads supplied by electronic power converters in industry has led to growing problems with the reliability of the power supply. Computers, adjustable speed drives, and automated manufacturing processes are very susceptible to voltage sags and brief outages. The need for greater power quality has prompted the end-users to install uninterruptable power systems and or other electronic power conditioning means to maintain the voltages within the susceptibility levels of the critical equipment. Advances in power semiconductor devices are making it possible for utilities to use a variety of power control equipment to raise power quality levels to meet these requirements [10]. A schematic diagram of the DVR incorporated into a distribution network is shown in Fig. 1.Vs is the source voltage, V1 is the incoming supply voltage before compensation, V2 is the load voltage after compensation, V_dvr, is the series injected voltage of the DVR, and is the line current. The restorer typically consists of an injection transformer, the secondary winding of which is connected in series with the distribution line, a voltage-sourced PWM Inverter Bridge is connected to the primary of the injection transformer and an energy storage device is connected at the dc-link of the inverter bridge [3].

![Fig. 1. Typical schematic of a power distribution system compensated by a DVR.](image)

However, the development in the DVR topologies, with direct converters, is not matched with that of the control algorithms. Most of them are controlled either by instantaneous comparison of the voltage at the PCC with a unit reference vector or simple feed forward control to adjust the duty cycle.

Since these topologies eliminate the dc link, the compensation depends directly on the voltage at the PCC, and each type of unbalance in the voltage at PCC imposes a limit on the compensation capability distinctly. Therefore, in this paper, a control scheme based on characterization of voltage sag is proposed for the topologies.
Characterization of voltage sags has not received due attention, though more developments have come with mitigation of voltage sags. The applications of classification and characterization of voltage sag have been limited to assessing the performance of various systems under sag and to present statistics. This paper demonstrates that characterizing can aid in efficient compensation. It helps in knowing the compensation capability of the topologies, since they are dependent on the input voltage waveforms. Insight on this capability helps in a flexible operation between the compensation schemes, that is, presag and inphase compensation.

II. PROPOSED TOPOLOGY

The schematic diagram of the proposed interphase ac–ac voltage sag supporter for correcting voltage sag in phase a is shown in Fig. 2. This voltage sag supporter is connected between the point of common coupling (PCC) and the load.

When the PCC experiences voltage sag, the compensator injects an appropriate voltage in series with the supply voltage to deliver the desired load voltage. This topology consists of two ac choppers and two isolation transformers in each phase. The transformers are connected such that the two chopper output voltages are added and isolated.

The required voltages from phase b and phase c are obtained by individual ac chopper and connected to primary of the each transformer. The added secondary voltage is then injected in series with the line to compensate the sag in phase a. Similarly, for phase b and phase c, individual sag supporters are provided.

![Fig. 2. Schematic diagram of the proposed interphase ac–ac voltage sag supporter.](image)

III. CHARACTERIZATION OF ALGORITHM

The proposed algorithm combines the merits of instantaneous symmetrical component theory and Fourier transform. The fundamental symmetrical components are calculated by taking Fourier transform of the instantaneous symmetrical components of the supply voltage at PCC. Instantaneous symmetrical components reflect the instantaneous changes in the supply voltage and so it is used to detect the disturbance in power system [9]. Instantaneous positive and negative sequence components are calculated by (1),

\[
\begin{bmatrix}
V_{a0} \\
V_{a1} \\
V_{a2}
\end{bmatrix} = \begin{bmatrix}
1 & 1 & 1 \\
1 & a & a^2 \\
1 & a^2 & a
\end{bmatrix} \begin{bmatrix}
V_a \\
V_b \\
V_c
\end{bmatrix}
\]

Where, \(a = e^{j120\degree}\), \(V_{a0}\), \(V_{a1}\) and \(V_{a2}\) are the instantaneous symmetrical components, \(V_a\), \(V_b\) and \(V_c\) are instantaneous supply voltages. The detection time however, varies with the number of phases affected. The sag in three phases is detected instantly. Sag in two and one phase takes utmost quarter and half cycle respectively. Being instantaneous in nature, error associated with the noise in voltage is more and the algorithm gives erroneous results in case of sags with unbalance in both magnitude and phase. The fundamental symmetrical component \(V_{ak}\) is calculated from its corresponding instantaneous values \(\bar{V}_{ak}\) as follows:

\[
V_{ak} = \frac{\sqrt{2}}{T_s} \int_0^{T_s} \bar{V}_{ak}(t) e^{-j(\omega t - \frac{\pi}{2})} dt
\]

Where \(K = 0, 1,\) and 2 represent zero, positive, and negative sequence, respectively; \(\omega\) is the fundamental frequency in radians per second and \(T_s\) is the system time period in seconds. Here, a half-a-cycle window is used (assuming that the even harmonics are negligible). The algorithmic flow chart as shown in figure 4.
a) Types of faults

![Diagram of types of faults](https://example.com/diagram)

While for sag type $C_5$, the line voltage is affected and phase-voltage is healthy. The sag type is identified using SCA by using the fact that a unique angle relation exists between positive- and negative sequence components for each type of sag [9, 10]. For sag, the angle between and is zero. Similarly, for $C_b$ and $C_c$, the angle is 120 and -120, respectively. The different sags are tabulated in Table I. The sag-type indicator is calculated using (3), [3] as given by

$$Ty = \frac{|\overline{V}_{a2} - |\overline{V}_{a1}|}{60^\circ}$$

(3)

Where $Ty$ is rounded to the nearest integer.

B. Characteristic Voltage

The characteristic voltage defines the three-phase voltage sag. For sag-type $C$ due to a phase-to-phase fault, characteristic voltage is along the affected line voltage; for other sag types, it is the affected phase voltage (sag types A, B, and D have the affected phase voltage as their characteristic voltage), as shown in Fig. 5. The characteristic voltage can be calculated from the sequence components and the sag-type indicator using (4).

$$\overline{V}_{ch} = \overline{V}_{a1} - b(6-\overline{Ty})\overline{V}_{a2} + a(6-\overline{Ty})\overline{V}_{a0}$$

(4)

Where $a = 1[120^0]; b = -a^2 = 1[60^0]$; and

$\overline{V}_{a1}, \overline{V}_{a2}$ and $\overline{V}_{a0}$ are the complex positive, negative and zero-sequence components, respectively. These components are extracted using (2). The moving-average technique is employed in (2) to have better dynamic response. The sag detection by the algorithm is done by tracking the magnitude of characteristic voltage. From Table II, it can be observed that except for sag type $C$, is the worst affected phase voltage. Therefore, when value goes below 0.9 p.u., SF is set. For the sag type $C$, since the characteristic voltage is along the line voltage, the phase voltages can be calculated using triangle properties involving the characteristic voltage, and
the characteristic phase angle $\phi$, that is, the angle of as shown in Fig. 6. Using the cosine rule, the magnitudes of phase voltages are calculated as follows:

\[
(\bar{V}_b)^2 = 0.25V^2 + 0.75\bar{V}_{ch}^2 -0.867V\bar{V}_{ch}\sin\phi \quad (5)
\]

\[
(\bar{V}_c)^2 = 0.25V^2 + 0.75\bar{V}_{ch}^2 +0.867V\bar{V}_{ch}\sin\phi \quad (6)
\]

Using the sine rule, the phase jump information is derived from (5) and (6)

\[
\phi_b = -60 + \sin^{-1}\left(\frac{\sqrt{3}V_{ch}}{2V_c}\right) \cos\phi
\]

\[
\phi_c = 60 - \sin^{-1}\left(\frac{\sqrt{3}V_{ch}}{2V_c}\right) \cos\phi
\]

Generally, the algorithm takes, at most, half-a-cycle to detect sag. However, the detection time varies with sag depth, that is, deeper sag can be detected even before half-a-cycle.

IV. REFERENCE VOLTAGE GENERATION

The reference voltage required to be injected at the affected phase is derived from the characteristic voltage. Fig. 5 shows the phasor diagram for presag compensation and in-phase compensation schemes.

![Fig. 6. Compensation scheme. (a) Presag compensation. (b) Inphase compensation.](image)

For the inphase compensation, the reference voltage is inphase with the characteristic voltage, and so only the magnitude is derived by (10) For sag type C, since characteristic voltage is along the line voltage, the reference voltage is calculated by using (8)

\[
|\bar{V}_{ref}| = |\bar{V}_{presag}| - |\bar{V}_{ch}| \quad (8)
\]

Where is the characteristic voltage before sag. The reference voltage for the inphase compensation is derived similarly. Knowing the reference voltage to be injected, the approximate voltage corresponding to it is generated by the sag supporter.

\[
\bar{V}_{ref} = \frac{\sqrt{2}}{2}(\bar{V}_{ch} - \bar{V}_{ch}') \quad (9)
\]

Here, an interphase ac–ac converter topology [1] is used for the study, since it accounts for phase-jump correction also. The switching scheme for the topology based on the characterization is discussed in the next section. The characteristics voltages for different types of sags are tabulated in table II.

V. SWITCHING LOGIC

The generation of switching logic for interphase ac–ac converter topology, which draws energy from the other two phases to compensate voltage dip in a phase, is elucidated here. There are three sectors I, II, and III as in Fig. 7(a), each comprised of two inverted phase voltages, and they represent phase- a, b, c and sag supporters, respectively. The phase- sag supporter (sector I) with active vectors and reference voltage is shown in Fig. 7(b).

![Fig. 7. Switching sequence. (a) Sectors of operation. (b) Sector I.](image)

The active vector can be realized by switching ON the phase-chopper and OFF the phase-chopper; while vector can be realized by switching OFF the phase-chopper and ON the phase-chopper. If both the choppers are ON, the resulting vector lies over the active vector [11]. The fourth vector, zero vectors, is placed at the origin and is obtained by withdrawing the switching pulses from both choppers.

\[
d_1\bar{V}_1 + d_2\bar{V}_2 = \bar{V}_{ref} \quad (10)
\]

Where and are duty cycles of the choppers corresponding to the active vectors and. The duty cycles are calculated as in (11) and (12), by resolving (10) in rectangular coordinates

\[
d_1 = \frac{[V_{ref}]\sin(\phi_0 + \theta)}{|V_1| \sin(\phi_0 + \phi)} \quad (11)
\]
\[ d_2 = \frac{|V_{ref}| \sin(\theta_1 - \theta)}{|V| \sin(\theta_1 + \theta_2)} \] (12)

Where is phase angle of the reference voltage, and are phase angles of the active vectors with respect to the active vector. Since, a buck ac–ac chopper is employed to realize the injected voltage, a limit is imposed on and as given by

\[ 0 \leq d_1 \leq 1 \quad \text{and} \quad 0 \leq d_2 \leq 1 \]

The calculated duty cycles and are given to series switches of the choppers across the phase voltages corresponding to the active vectors and, that is, phase- and voltages, for a phase-sag supporter.

VI. SIMULATION STUDIES

To test the efficacy of the algorithm, two asymmetrical sags, and symmetrical sag are simulated using MATLAB, and the results are shown in Figs. 8–10. As discussed in the aforementioned sections, the magnitudes of the symmetrical components (\(V_{a1}, V_{a2}\), and \(V_{a0}\)), sag-type indicator, characteristic voltage, reference voltage in the affected phases, and the duty cycle of the choppers (\(d_1\) and \(d_2\)) in the corresponding sag supporters are estimated for three sag types, and their corresponding per-unit values are listed in [11].
In this paper, a control scheme based on the characterization of voltage sag is proposed. It is tested on inter-phase ac–ac converter topology and it is found that the scheme besides compensation gives insight on the limits on compensation imposed by various sag types. Therefore, it aids in the flexible compensation by switching between pre-sag and in-phase compensation. The scheme provides 100% compensation for type sag, and for all other types, compensation up to 50% sag magnitude with phase jumps ranging from 60° to 60° for inter phase ac–ac topology. The algorithm takes; at most, half a cycle to compensate and it works in the presence of harmonics and unbalance, since the Fourier transform is employed to extract the fundamental component.

VII. CONCLUSION

In this paper, a control scheme based on the characterization of voltage sag is proposed. It is tested on inter-phase ac–ac converter topology and it is found that the scheme besides compensation gives insight on the limits on compensation imposed by various sag types. Therefore, it aids in the flexible compensation by switching between pre-sag and in-phase compensation. The scheme provides 100% compensation for type sag, and for all other types, compensation up to 50% sag magnitude with phase jumps ranging from 60° to 60° for inter phase ac–ac topology. The algorithm takes; at most, half a cycle to compensate and it works in the presence of harmonics and unbalance, since the Fourier transform is employed to extract the fundamental component.
